Key Words. Mesenchymal stem cells • Differentiation • Three-dimensional • Patterning

ABSTRACT

The ability of stem cells to differentiate into specified lineages in the appropriate locations is vital to morphogenesis and adult tissue regeneration. Although soluble signals are important regulators of patterned differentiation, here we show that gradients of mechanical forces can also drive patterning of lineages. In the presence of soluble factors permitting osteogenic and adipogenic differentiation, human mesenchymal stem cells at the edge of multicellular islands differentiate into the osteogenic lineage, whereas those in the center became adipocytes. Interestingly, changing the shape of the multicellular sheet modulated the locations of osteogenic versus adipogenic differentiation. Measuring traction forces revealed gradients of stress that preceded and mirrored the patterns of differentiation, where regions of high stress resulted in osteogenesis, whereas stem cells in regions of low stress differentiated to adipocytes. Inhibiting cytoskeletal tension suppressed the relative degree of osteogenesis versus adipogenesis, and this spatial patterning of differentiation was also present in three-dimensional multicellular clusters. These findings demonstrate a role for mechanical forces in linking multicellular organization to spatial differentials of cell differentiation, and they represent an important guiding principle in tissue patterning that could be exploited in stem cell-based therapies. STEM CELLS 2008; 26:2921–2927

INTRODUCTION

Morphogenesis involves a complex coordination of spatial rearrangements that give rise to numerous complex structures, and the differentiation of stem cells into the many cell types that populate these structures [1, 2]. This orchestration of patterned differentiation within developmental structures is thought to be regulated primarily by spatial gradients of diffusible factors known as morphogens [3–6]. It is generally thought that these morphogens can simultaneously control morphologic changes and differentiation programs in cells, such that the appropriate cell types attain their corresponding locations within complex tissues.

In addition to such morphogenetic gradients, it is also clear that gradients in mechanical forces, which could contribute to the process of morphogenesis, also exist within developing embryos. During many of the massive rearrangements that occur in early development, such as convergence and extension, neural tube formation, dorsal closure, and anterior gut formation, mechanical forces appear to be involved [7–10]. Furthermore, recent work suggests that such mechanical factors appear to contribute to the specification of adult mesenchymal and embryonic stem cells to various lineage fates [11–15]. In the context of mesenchymal stem cells (MSCs), it has been shown that progressively increasing RhoA-mediated cytoskeletal tension can alter lineage specification from adipocytes or neural precursors to myocytes and osteoblasts [11, 12], raising the possibility that spatial gradients of stress within a structure could act to pattern differentiation. We recently introduced an approach to generate such force gradients in micropatterned sheets of cells and demonstrated that such gradients can drive patterns of cell proliferation in endothelial and epithelial cells [16]. It remains unclear, however, whether such gradients of forces can also determine patterns of lineage specification of stem cells.

Here, we demonstrate that multicellular aggregates of MSCs undergo lineage specification as a function of aggregate geometry and of cell position within the aggregate. Cells on the outer edge of simple sheets committed to an osteogenic lineage, whereas interior MSCs differentiated to adipocytes. Three-dimensional structures also exhibited partitioning of fat and bone. These patterns appear to result from nonuniform patterns in mechanical stress determined by multicellular shape and generated by the actin-myosin cytoskeleton. Understanding these mechanical patterning effects not only will improve our understanding of in vivo differentiation but also may provide important insights for optimizing stem cell-based therapies.

MATERIALS AND METHODS

Materials

The following reagents were purchased from the following suppliers: polydimethylsiloxane (PDMS) (Sylgard 184; Dow Corning, 1066-5099/2008/$30.00/0 doi: 10.1634/stemcells.2008-0432

**Cell Culture**

Human mesenchymal stem cells (32-year-old male and 21-year-old male; Cambrex, Walkersville, MD, http://www.cambr.exc) were cultured in growth medium consisting of Dulbecco’s modified Eagle’s medium supplemented with 10% fetal bovine serum, 0.3 mg/ml l-glutamine, 100 units/ml penicillin, and 100 μg/ml streptomycin. Adipogenic induction and osteogenic differentiation media were purchased from Cambrex. Medium was changed every 3 days except when cells were treated with blebbistatin and Y-27632, in which case the medium was replaced daily. When infected with adenoviruses containing GFP and ROCKΔ3, cells were incubated with the virus overnight and used the next day.

**Pattern Generation**

Patterns of fibronectin on PDMS-coated coverslips were generated by microcontact printing [11]. The regions surrounding the patterns were rendered nonadhesive by incubating the coverslips in F127 Pluronic (BASF, Ludwigshafen, Germany, http://www.basf.com) [18]. MSCs were seeded onto the coverslips at a density of 20,000 cells per cm². After an initial 24 hours in growth medium, the cells were then cultured in either adipogenic or osteogenic medium or in a 1:1 mixture of both for the subsequent 14 days unless otherwise indicated.

**Staining**

After 14 days, the cells were fixed in 3.7% paraformaldehyde and stained for alkaline phosphatase using Fast Blue RR Salt/naphthol (PBS25-10CAP, 855-20ML; Sigma-Aldrich, St. Louis, http://www.sigmaaldrich.com), lipid droplets with 3 mg/ml oil red O (O-0625; Sigma-Aldrich) in 60% isopropanol, and nuclei with 4,6-diamidino-2-phenylindole (DAPI; D1306; Invitrogen, Carlsbad, CA, http://www.invitrogen.com). To assay for differentiation after 5 days in culture, the transcription factors peroxisome proliferator-activated receptor γ (PPARγ) and cbfa-1 were stained for. After Triton-extracting the soluble component and fixing with 3.7% paraformaldehyde, the samples were blocked overnight with 33% goat serum. The coverslips were then incubated in rabbit anti-PPARγ (sc-7196; Santa Cruz Biotechnology Inc., Santa Cruz, CA, http://www.scbt.com) and rat anti-cbfa-1 (MAB2006; R&D Systems Inc., Minneapolis, http://www.rdsystems.com) antibodies for 1 hour. After three phosphate-buffered saline (PBS) washes the coverslips were incubated in 488-goat anti-rabbit and 647-goat anti-rat (A-11034, A-21247; Molecular Probes, Eugene, OR, http://probes.invitrogen.com) secondary antibodies, as well as DAPI. After three PBS washes, the coverslips were mounted.

**Microscopy and Analysis**

An Eclipse TE-200 microscope (Nikon, Tokyo, http://www.nikon.com) with a ×10 objective was used to capture images of alkaline phosphatase and oil red O-stained patterns. An Axiovert 200M microscope (Carl Zeiss, Jena, Germany, http://www.zeiss.com) with a ×40 objective was used to capture fluorescence images of transcription factor-stained patterns. Because the patterns were larger than the ×40 field of view, multiple images were captured and stitched to form a single image of the entire pattern. Four concentric circles were drawn around the circular patterns to divide them into four zones of equal area. Cells that stained positive for oil red O or had PPARγ in their nuclei were scored as adipocytes, whereas cells that stained positive for alkaline phosphatase or had cbfa-1 in their nuclei were counted as osteogenic cells. Cells with neither stain were scored as undifferentiated. The cells were then counted and used to calculate the percentage of each cell type in each zone. Means were calculated from three experiments, with at least three circles analyzed from each. Bar graphs show mean ± SEM. Statistical significance between means of different lineages within a zone or between means of the same cell type in two different zones was calculated using Student’s t test.

**Measurement of Traction Forces**

Traction forces were measured using microfabricated postarray detectors as previously described [19]. Briefly, microfabricated postarray detectors (mPADs) were microcontact printed with fibronectin so that cells cultured on the devices spread and conformed to the printed patterns. The cells were cultured on mPADs in the presence of growth medium for 24 hours before being fixed in 3.7% paraformaldehyde. Images of post tips and bases were captured using a Carl Zeiss Axiovert XX microscope with a ×40 objective, stitched to form the pattern, and used to calculate the post deflections and, from them, the forces exerted on the posts by the cells. Statistical significance between force distributions was calculated by using the Wilcoxon rank-sum test.

**Three-Dimensional Structure Generation and Analysis**

Molds were produced by pushing PDMS stamps with relief features, cast from photolithographically fabricated Su-8 templates, onto prepolymer PDMS in oxygen plasma-treated Petri dishes. After curing for 2 hours at 60°C, the stamps were removed, leaving a mold with wells. Prior to cell seeding, the molds were immersed in F127 Pluronic to render the PDMS nonadhesive. Prepolymer type I collagen was added to the molds at 4°C. The molds were placed in a vacuum chamber to remove air bubbles trapped at the bottom of the well. MSCs were trypsinized, resuspended in gel precursor at a density of 2 × 10⁶ cells per milliliter, and then added to the molds. The molds were then centrifuged at 1,200 rpm for 2.5 minutes to pool the cells into the wells. After the excess gel was aspirated, the mold was exposed to a temperature of 37°C to polymerize the collagen. One percent low-melting-point liquid agarose was added to the molds to encase the microgel structures. The agarose was gelled at 4°C for 1 minute, and fresh culture medium was added to the dishes.

Microgels were stained for alkaline phosphatase and lipid droplets as described above, enased in Tissue-Tek OCT Compound (Electronic Microscopy Sciences, Hatfield, PA, http://www.emdiasium.com), and snap frozen in liquid nitrogen. Cross-sections were taken using a Leica CM 1850 cryostat (Leica, Heerbrugg, Switzerland, http://www.leica.com) and imaged as described above. A MATLAB program was written to analyze the images. First, the program created two binarized images, one red, representing adipogenesis, and one blue, representing osteogenesis, from the original color image (supplemental online Fig. 1). Next, one-pixel “shells” starting from the perimeter of the structure and terminating at its center were generated. Finally, each shell was compared against the two binarized color images to compute the percentages of red and blue pixels in the shell. The percentages were either plotted versus shell distance from the center (supplemental online Fig. 2) or used to determine the percentages of fat and bone in four concentric zones of equal area. Means were calculated from three experiments, with cross-sections of at least three structures analyzed from each. Graphs show mean ± SEM. Statistical significance between means of different lineages within a zone or between means of the same cell type in two different zones was calculated using Student’s t test. Statistical significance between curves in supplemental online Figure 2 was calculated by applying the sign test to the paired experiments.
RESULTS

Patterning of Lineages Occurs Within Multicellular Aggregates

To produce monolayer sheets of human MSCs in a circular shape, we seeded cells onto substrates engineered with arrays of adhesive islands generated by microcontact printing fibronectin onto coverslips (Fig. 1A, 1B). After cells were allowed to attach and form a sheet overnight, MSCs were exposed to a 1:1 mixture of adipogenic and osteogenic induction media, and after 14 days they were costained for lipid droplets to indicate adipogenesis and alkaline phosphatase to indicate osteogenesis. Cells within the interior of these circles contained lipid droplets (red), whereas those at the edge stained positively for alkaline phosphatase (blue) (Fig. 1C). This patterned segregation of lineages emerged in all sizes of circles examined (250–1,000 μm diameter; approximately 20–250 cells) (Fig. 2A) but did not occur in cells exposed to growth, adipogenic, or osteogenic medium alone (Fig. 1D–1F). To quantify the distribution of lineages in these monolayers, we superimposed four concentric circles on each monolayer to divide it into four zones of equal area and counted the cells within each zone that were positive for each marker (Fig. 1G). In the innermost zone, more than 85% of the cells had lipid droplets, and approximately 5% were alkaline phosphatase-positive, whereas in the outermost zone, less than 1% were adipocytes and 70% exhibited an osteogenic phenotype (Fig. 1H). Interestingly, patterned differentiation appears to scale with size, where the relative radii at which cell fates segregate are proportional to the size of the circle (Fig. 2B).

Although lipid accumulation is diagnostic for adipogenesis, alkaline phosphatase is not specific for osteogenesis. Although detection of calcium deposition can be diagnostic for osteogenic differentiation, it was not possible in this setting because cells escape the constraints of patterning before calcium deposition is typically seen in these cells (>21 days). As such, we confirmed our findings using two transcription factors for adipogenesis and osteogenesis: PPARγ and cbfa-1/runx2, respectively. PPARγ is expressed within days of addition of adipogenic medium [20] and is a transcription factor required for adipogenesis [21], activating many of the genes necessary for fatty acid metabolism, such as lipoprotein lipase and the fatty-acid-binding protein ap2 [22]. cbfa-1/runx2 is similarly expressed at early time points during osteogenesis and is a transcription factor essential for osteoblast differentiation [23, 24], inducing expression of bone matrix-generating genes, such as osteopontin, osteocalcin, type I collagen [25, 26], and alkaline phosphatase [26, 27]. Circular monolayers stained for these markers after only 5 days in culture demonstrated 47% of interior cells with

Figure 1. Patterned segregation of lineages occurs within multicellular aggregates. (A): Schematic showing substrate preparation by microcontact printing. (B): Phase image of mesenchymal stem cells (MSCs) on 1-mm circular patterns at day 0. (C–F): One-mm circular MSC aggregates stained for fat droplets (red) and alkaline phosphatase (blue) after 14 days in mixed media (C), growth medium (D), adipogenic medium alone (E), or osteogenic medium alone (F). (G): Concentric circles were placed over circular aggregates to divide them into four zones of equal area. Nuclei were labeled with 4,6-diamidino-2-phenylindole to determine cell location. (H): Bar graph showing fraction of each cell type within each zone after 14 days in mixed media. (I): Bar graph showing fraction of each cell type within each zone determined by assaying for transcription factors after 5 days in mixed media. * indicates p < 0.05 for all comparisons of the same cell type across different zones or different cell types within the same zone, except for those marked with #. Scale bars = 250 μm. Abbreviation: PDMS, polydimethylsiloxane.

Figure 2. Partitioning of differentiation scales with size. (A): Circular mesenchymal stem cell aggregates with diameters of 250, 500, 750, and 1,000 μm stained for oil droplets (red) and alkaline phosphatase (blue) after 14 days in mixed media. (B): Bar graph shows fraction of each cell type within each zone for circular aggregates of all four sizes. Scale bars = 250 μm. Abbreviations: adipo, adipogenic; osteo, osteogenic.
PPARγ in the nucleus and 2% with nuclear cbfa-1/runx2 (Fig. 11). In contrast, 8% of edge cells exhibited nuclear PPARγ, whereas more than 73% were positive for cbfa-1/runx2. These results confirmed the partitioning of differentiation within these structures.

Aggregate Geometry Affects Patterning of Differentiation

To assess the effect of monolayer geometry on the distribution of adipogenic and osteogenic lineages, MSCs were confined to different shapes. Squares, rectangles, ellipses, and half-ellipses all resulted in adipogenesis in the interior and osteogenesis at the edges, regardless of whether the edges were straight, cornered, or curved (Fig. 3A–3D). It was previously observed that the inner, concave edges of annuli exhibited low proliferation compared with outer edges of solid patterns, suggesting that these inner edges may have different effects [16]. Indeed, MSC monolayers cultured in such patterns exhibited osteogenesis at the outer edge and adipogenesis at the inner edge (Fig. 3E, 3F).

Role of Tension in Patterning of Differentiation

Myosin-generated cytoskeletal tension has been implicated in regulation of spatial patterning of a variety of responses, such as proliferation and gastrulation [7, 16]. To determine whether spatial differentials in cellular forces arose in our multicellular sheets and whether such forces correlated to the observed patterns of MSC differentiation, we plated MSCs in sinusoidal monolayers onto mPAD substrates, which consist of an array of elastomeric microneedles that report local traction forces [19] (Fig. 4A). Indeed, the magnitudes of forces at the convex edge of the undulations were nearly three times those at the concave edge (66.3 vs. 23.6 nanonewtons [nN] per post) and mirrored the pattern of osteogenic versus adipogenic differentiation. Plotting the distribution of forces at convex edges revealed a peak at 110 nN, compared with 40 nN at concave edges (Fig. 4B). Thus, the geometry of the multicellular structure can give rise to local gradients of mechanical forces.

To test whether the high tension generated at convex edges is responsible for increased osteogenesis at those edges, we treated MSCs in such patterns with the nonmuscle myosin II inhibitor blebbistatin. Inhibiting myosin-generated tension abrogated osteogenesis almost completely, while preserving adipogenesis (Fig. 5A, 5B, 5E, 5F). Given possible nonspecific effects of the inhibitor, we confirmed that inhibition of the upstream regulators of myosin, Rho-kinase (ROCK) with Y27632 and myosin light chain kinase with ML-7, also resulted in specific suppression of osteogenesis (Fig. 5C, 5D, 5G, 5H).
These results suggest that localized patterns of cytoskeletal tension within these multicellular sheets trigger patterns of differentiation to different lineages.

**Patterning of Differentiation in Three-Dimensional Structures**

The patterning of differentiation that we observed may arise as a specific response to the micropatterned, flat substrates and may not represent what occurs when cells are embedded within three-dimensional contexts. To determine whether patterned differentiation can occur in three-dimensional matrix, we developed a method to construct three-dimensional, multicellular structures of MSCs. PDMS molds produced from photolithographically fabricated templates with wells of controlled dimensions were used to create MSC-laden collagen constructs of defined three-dimensional geometries (Fig. 6A). MSCs suspended in unpolymerized collagen type I were pooled into the wells by centrifugation, and excess collagen was removed before polymerization. The resulting constructs were then released and encased in agarose to allow culture without diffusion barriers. These three-dimensional structures could be peeled out of the template while retaining their integrity (Fig. 6B). After 14 days in mixed media, cells at the edge of the constructs differentiated to an osteogenic lineage (as indicated by alkaline phosphatase staining), whereas those at the center underwent adipogenesis (as indicated by lipid droplet staining) (Fig. 6C). To confirm that patterning of differentiation occurred throughout the structures, they were sectioned and imaged (Fig. 6D, 6E). To quantify the distribution of lineages in these structures, the spatial distribution of red and blue pixels within their cross-sections was determined (supplemental online Fig. 1). In the innermost zone, MSCs predominantly underwent adipogenesis, whereas cells switched to osteogenic fate in the outermost zone (Fig. 7A, 7E). Although endogenous forces could not be measured within these structures, we examined whether up- or downregulating cytoskeletal tension altered the patterns of differentiation. Constructs treated with blebbistatin decreased osteogenesis, mimicking our findings on flat substrates (Fig. 7B, 7F; supplemental online Fig. 2A). Expressing ROCKΔ3, a mutant form of ROCK that is constitutively active and results in high myosin activity, resulted in a thicker layer of osteogenesis at the edge of the structures (Fig. 7C, 7D, 7G, 7H; supplemental online Fig. 2B). These results suggest that localized patterns of cytoskeletal tension within these multicellular sheets trigger patterns of differentiation to different lineages.

Figure 5. Cytoskeletal tension is necessary for patterned differentiation. (A–D): Circular mesenchymal stem cell aggregates stained for oil droplets (red) and alkaline phosphatase (blue) after 14 days in mixed media without inhibitor (A) or in the presence of 50 μM blebbistatin (B), 10 μM Y-27632 (C) or 10 μM ML-7 (D). (E–H): Bar graphs showing fraction of each cell type within each zone. * indicates p < .05 compared with corresponding mean in the untreated condition (E). Scale bar = 250 μm.

Figure 6. Three-dimensional multicellular structures undergo partitioning of differentiation. (A): Schematic showing method to create three-dimensional multicellular structures of mesenchymal stem cells (MSCs). (B): Phase image of MSCs in three-dimensional structures at day 0. (C): Phase image of a three-dimensional MSC structure stained for oil droplets (red) and alkaline phosphatase (blue) after 14 days in mixed media. (D, E): Longitudinal section and cross-section of MSC multicellular structures. Scale bars = 250 μm. Abbreviation: PDMS, polydimethylsiloxane.
During morphogenesis, cells execute massive structural rearrangements in a tension-dependent manner. Specification also occurs in three-dimensional matrices in a patterned manner, demonstrating that partitioning of lineage decisions and therefore coordinate tissue development in a tension-dependent manner.

**DISCUSSION**

During morphogenesis, cells execute massive structural changes that lead to new tissue forms while simultaneously differentiating to populate those structures. In the adult, cells reside in specific locations within multicellular structures and are subjected to a wide variety of stresses, such as shear, stretch, tension, and compression. The findings presented here suggest a direct link connecting multicellular form, stress distributions, and lineage fate of differentiating stem cells. This link may restrict the differentiation potential of stem cells to specific lineage fates as a function of position within a structure. It is interesting that in our three-dimensional cylinders, MSCs form a hollow shaft of bone with a core of fat, not unlike the anatomy universal to all vertebrate long bones [28]. Such hardwiring between tissue form and fate may provide a key mechanism to prevent spurious fate decisions and therefore coordinate tissue development in a variety of settings. For example, geometric factors present in the bone microenvironment could regulate the balance of adipogenic and osteogenic differentiation critical to bone homeostasis. The loss of trabecular bone in osteoporosis may not only be a primary defect in the disease but also could feed back to alter the balance of convex and concave surfaces where differential forces exist, thereby further exacerbating any population imbalances. Whether such geometric disturbances actually contribute to such diseases remains to be explored. Furthermore, in the context of engineering tissues for regenerative medicine, such constraints may limit our ability to generate differentiated tissues with arbitrary shapes.

Our findings also indicate that mechanical forces generated by contractile activity of cells provide the patterning cues that couples form to fate decisions. The existence of such cytoskeletal forces has been implicated in numerous developmental processes, such as germ band elongation, primary invagination, and neural convergent extension [29–31]. Cytoskeletal tension had previously been shown to result in mechanical loading of three-dimensional matrices [32], which can feed back to modulate cell behavior, such as differentiation of fibroblasts into myofibroblasts [33]. Here, we demonstrated that gradients of stress are generated simply by the existence of tissue geometry, even when massive rearrangements are not occurring, and therefore should be considered as a potential candidate for driving patterns in cell function. Importantly, although such force gradients appear to be omnipresent in the experimental system presented here, likely as a result of basal contractility of MSCs, our studies also suggest that form and fate could be decoupled or engaged to a different extent through genetic or environmental regulation of cellular contractile activity and that such manipulations can be exploited in tissue engineering. Although our studies implicate force as one factor that can be patterned by multicellular form, others have reported localized gradients in soluble morphogens also patterned by multicellular structures [34–36]. Together, gradients in forces and morphogens, then, likely provide the key links that orchestrate the shape changes that occur during morphogenesis and the coordinate spatial differentials in cell differentiation.

**CONCLUSION**

The findings presented here suggest a role for mechanical forces in linking multicellular organization to spatial differentials of cell differentiation. Understanding how fate decisions are tied to tissue form will provide a better appreciation of how cells orchestrate morphogenetic processes, as well as roadmap for directing stem cell fates in regenerative therapies. Understanding how fate decisions are tied to tissue form will provide a better appreciation of how cells orchestrate morphogenetic pro-
cesses, as well as a roadmap for directing stem cell fates in regenerative therapies.
