Reduced streamflow in water-stressed climates consistent with CO₂ effects on vegetation

Anna M. Ukkola¹, I. Colin Prentice¹,², Trevor F. Keenan¹, Albert I. J. M. van Dijk³, Neil R. Viney⁴, Ranga B. Myneni⁵ and Jian Bi⁵

Global environmental change has implications for the spatial and temporal distribution of water resources, but quantifying its effects remains a challenge. The impact of vegetation responses to increasing atmospheric CO₂ concentrations on the hydrologic cycle is particularly poorly constrained. Here we combine remotely sensed normalized difference vegetation index (NDVI) data and long-term water-balance evapotranspiration (ET) measurements from 190 unimpaired river basins across Australia during 1982–2010 to show that the precipitation threshold for water limitation of vegetation cover has significantly declined during the past three decades, whereas sub-humid and semi-arid basins are not only ‘greening’ but also consuming more water, leading to significant (24–28%) reductions in streamflow. In contrast, wet and arid basins show nonsignificant changes in NDVI and reductions in ET. These observations are consistent with expected effects of elevated CO₂ on vegetation. They suggest that projected future decreases in precipitation are likely to be compounded by increased vegetation water use, further reducing streamflow in water-stressed regions.

Experiments have shown that elevated atmospheric CO₂ affects vegetation productivity and water use. CO₂ is the substrate for photosynthesis, and concentrations above current ambient levels stimulate carbon assimilation by plants. This CO₂ fertilization effect should in principle lead to increased biomass and green vegetation cover (‘greening’). Simultaneously, increasing CO₂ lowers stomatal conductance, reducing water loss through leaves. Reduced stomatal conductance and/or stimulated photosynthesis lead to enhanced water-use efficiency, the amount of water required to produce a unit of biomass. The effect of CO₂ on vegetation is commonly expected to manifest most strongly in water-limited environments, where moisture is the main limitation on plant growth. However, not all studies show a strong link between aridity and the strength of the CO₂ effect, and the magnitude of associated greening and water savings are generally not well constrained across species and ecosystems.

CO₂-induced structural and physiological changes in vegetation potentially have consequences for water resources. CO₂ fertilization and associated greening tend to increase vegetation water consumption by increasing the amount of transpiring leaf area, whereas reduced stomatal conductance tends to decrease transpiration per unit leaf area—two effects with opposing consequences for streamflow. Furthermore, increased vegetation cover can change the partitioning of rainfall into rainfall interception, infiltration and runoff, while shading by increased foliage cover may lead to reductions in soil evaporation by decreasing the amount of radiation reaching the ground surface. It remains unresolved whether these various processes in combination have led to a detectable imprint in ET or streamflow. At the global scale, both decreases and increases in ET due to CO₂ have been reported and the results seem to be data- and model-dependent. The direction and magnitude of the CO₂ effect on ET and streamflow thus remains poorly understood at catchment and regional scales. This situation is compounded by difficulties in estimating ET at large scales.

We investigated the correlates and potential causes of long-term changes in vegetation across Australia using remotely sensed NDVI. NDVI has been found to relate to primary productivity, foliage cover and biomass and has been widely employed to quantify vegetation trends and processes. We also examined long-term changes in ET and streamflow in unregulated, unimpaired Australian river basins in climates of varying aridity. ET was assessed by the water-balance method, which relies directly on observations of precipitation and streamflow.

We first investigated the spatial distribution of long-term changes in NDVI across Australia. Large areas of Australia have undergone greening during 1982–2010 (Fig. 1a); precipitation explained about 50% of these trends (calculated as the coefficient of determination from a linear regression of NDVI and precipitation trends). Strong greening was observed, particularly in water-limited areas (marked by positive NDVI–precipitation correlation; Fig. 1b), where 65% of significant (P ≤ 0.5) NDVI trends were positive (excluding areas of significant precipitation increase).

We then quantified changes in the vegetation–precipitation relationship in areas of natural and semi-natural vegetation across Australia. By examining temporal changes in the upper 95th percentile bound for the spatial relationship between annual precipitation and NDVI (Fig. 2, see Methods) we identified long-term changes in the maximum NDVI attainable for a given amount of precipitation, and the extent of vegetation water limitation. We found that the maximum NDVI attainable for a given precipitation level has increased over time in water-limited areas (Fig. 3a; P = 0.0059). This implies that a given amount of precipitation has sustained greater levels of plant production over time, which is consistent with CO₂ fertilization. In addition, the breakpoint marking the precipitation limit where vegetation ceases to be
water-limited decreased over time (P = 0.039; Fig. 3b). This trend indicates a relaxation of vegetation water limitation, consistent with the increased water-use efficiency that is expected to accompany rising CO₂.

To analyse long-term changes in vegetation and hydrology at the river-basin scale, we calculated CO₂ sensitivity coefficients for NDVI and ET across basins grouped into four aridity categories (wet, sub-humid, semi-arid and arid), as theory would predict that a CO₂ effect should differ systematically between the categories. The sensitivity coefficients express the fractional change in ET and NDVI per unit fractional change in CO₂ concentration (after correcting ET and NDVI for precipitation and potential evapotranspiration (PET) variations, as detailed in Methods). A positive sensitivity coefficient of ET to CO₂ of comparable magnitude to that of NDVI would indicate that a CO₂ stimulation of vegetation cover dominates over a reduction in stomatal conductance with rising CO₂, owing to an increased surface area of leaves for transpiration and rainfall interception. A negative sensitivity coefficient of ET to CO₂ (which can be of magnitude up to −1 at high CO₂ concentrations) indicates that the reduction in stomatal conductance with rising CO₂ dominates over the CO₂ stimulation of vegetation cover. We predict theoretical sensitivities around −0.6 in wet climates and −0.4 in arid climates owing to the effect of a reduction in stomatal conductance with rising CO₂ on ET (see Methods).

In sub-humid and semi-arid basins, the data show a significant positive sensitivity coefficient of ET and NDVI to CO₂ (0.44 ± 0.14 and 0.18 ± 0.08 for ET, 0.10 ± 0.04 and 0.18 ± 0.11 for NDVI, respectively; Fig. 4a). In sub-humid basins, the sensitivity coefficient of ET to CO₂ is similar to the sensitivity coefficient of ET to precipitation (0.64 ± 0.05 calculated from uncorrected data; Supplementary Fig. 2a and Supplementary Table 2). In semi-arid basins, the sensitivity coefficient of ET to CO₂ is about a fifth of its sensitivity coefficient to precipitation (0.86 ± 0.02). The CO₂ concentration increased by 48 ppm during the period 1982–2010. Based on the sensitivity coefficients, the CO₂-induced ET increases during this time period amounted to 43 mm in sub-humid and 14 mm in semi-arid basins on average. These translate to a 6% and 2% increase, respectively, in mean annual ET (Fig. 4b). The relative changes in mean annual ET due to CO₂ are similar to those due to precipitation (−6% and 1%, respectively; Supplementary Fig. 2b and Supplementary Table 5) and significantly larger than those due to PET (−1% and 0%, respectively; Supplementary Fig. 2b and Supplementary Table 6). Together with significant positive NDVI sensitivity coefficients to CO₂ (Fig. 4a), this finding suggests an effect of rising CO₂ on both NDVI and ET, and that the fertilization effect dominates over stomatal closure.

In wet basins, the sensitivity coefficient of ET to CO₂ was found to be negative (−0.42), consistent with theoretical predictions (see Methods), but this value was not statistically distinguishable from zero (Fig. 4a). No greening was detected. In wet environments, vegetation cover is nearly complete and expected to be limited by light and nutrients rather than water. Thus limited greening should occur, and the principal effect of CO₂ on ET would be a decline due to reduced stomatal conductance.

We also found negative but nonsignificant CO₂ coefficients on ET (−0.33 ± 0.55) and NDVI (−0.11 ± 0.34) in arid basins (Fig. 4a). This finding runs counter to the common expectation that CO₂ effects should be most pronounced in the most strongly water-limited environments. However, it is consistent with field experimental evidence showing no long-term change in biomass or water-use efficiency under elevated CO₂ in a desert environment. This lack of a detectable response has been attributed to a high frequency of years with very low precipitation, inhibiting any sustained increase in vegetation biomass. Warm arid areas also tend to harbour a larger proportion of C₄ grasses, which we estimate to

Figure 1 | Spatial patterns of vegetation greening. a. Pixel-by-pixel linear trends in annual NDVI. b. Areas of water-limited vegetation, determined as pixels with significant (P ≤ 0.10) positive annual NDVI-precipitation correlations. Nonsignificant or negative correlations were masked out from b. Farmlands, irrigated areas and wetlands have been masked out from both panels.

Figure 2 | Illustration of the breakpoint regression method. The first regression line (upward-sloping dashed line) represents the maximum NDVI attainable for a given amount of precipitation, under water-limited conditions. The breakpoint (the point at which the slope changes direction, at approximately 900 mm yr⁻¹ precipitation) signifies the threshold where vegetation ceases to be water-limited. The data are the running mean 1983–1987. The coloured bands show the different percentiles.
considering the CO₂ sensitivities for these regions, is consistent with a response to CO₂. Given the actual observed declining trend in precipitation in the sub-humid basins (−3 mm yr⁻¹, P < 0.001; Supplementary Fig. 4), increasing CO₂ is likely to have aggravated the pressure on water resources in these basins. In arid basins, a 4% decrease in ET would have led to a 132% increase in streamflow and in wet basins a 5% ET decrease would have led to a 5% increase in streamflow. However, neither effect is statistically significant, so we cannot detect a CO₂ effect on streamflow in either the wettest or the driest regions on the basis of these measurements.

Our results provide evidence that rising atmospheric CO₂ has led to observable changes in terrestrial ecosystems and hydrology across a large part of Australia, with implications for carbon and water cycling at regional to global scales. Terrestrial ecosystems worldwide at present withdraw about a quarter of all anthropogenically emitted CO₂ when averaged over a decade²⁻². A recent study³ showed that semi-arid areas, particularly in Australia, play a major regional and even global role in modulating interannual variations in the rate of terrestrial carbon uptake. Increased carbon sequestration rates due to CO₂-induced greening in these semi-arid regions may lead to enhanced uptake of CO₂ from the atmosphere in the future. Furthermore, the response to rising CO₂ has the potential to either magnify or counteract future changes in precipitation. Precipitation is projected to decline in semi-arid and arid Australia during the twenty-first century⁴, and increasing CO₂ is thus likely to put further pressure on water resources in already water-stressed regions. Our results may have similar implications for other water-limited subtropical regions in the Mediterranean, southern Africa and the Americas, where precipitation is also projected to decline with increasing global temperature⁴. We conclude that increasing atmospheric CO₂ is likely to have left a detectable imprint on Australian ecosystems and hydrology, and such responses should be taken into account in future projections of water resources.

Methods

Core data sets. Normalized difference vegetation index. We obtained a time series of third-generation NDVI (NDV13g) from the Global Inventory Modelling and Mapping Studies (GIMMS; ref. 24). This data set is gridded at 0.083° spatial resolution and was averaged from biweekly to annual time steps. The annual average for a given grid cell was determined only if >80% of biweekly values were available and was set to missing otherwise. Similarly, pixel trends were calculated only for pixels with annual time series >80% complete. Basin-specific NDVI values were obtained by averaging gridded data over basin areas.

Climatic variables. Monthly climatic fields (precipitation, minimum and maximum air temperature and shortwave radiation) were obtained from the ANCLIM archive23. The Australia-wide data are gridded at 0.05° spatial resolution and were produced by the ANUSPLIN software package22,24 from meteorological station data using a thin-plate smoothing spline.

An annual time series of atmospheric CO$_2$ concentrations was obtained from National Oceanic and Atmospheric Administration Earth System Research Laboratory (NOAA ESRL; http://www.esrl.noaa.gov/gmd/ccgg/trends). The data report the mean annual CO$_2$ concentration measured at Mauna Loa observatory in parts per million. We ignored latitudinal differences in CO$_2$ concentration as these are small compared to the signal of interest.

Potential evapotranspiration (PET) was calculated using the Priestley–Taylor method as in ref. 27, using inputs of shortwave radiation and the mean of minimum and maximum air temperature from the ANCLIM archive. The Priestley–Taylor method has been shown to be appropriate for estimating large-scale PET (refs 28,29) and has been adopted in other basin-scale studies30,31.

Water-balance evapotranspiration. Water-balance evapotranspiration was calculated as the difference of observed annual precipitation and streamflow integrated over the river basin area. The water-balance method remains the most firmly observationally based estimator of ET, but assumes negligible changes in soil water storage at annual or decadal timescales (see Supplementary Section 1 for further discussion). Streamflow time series were acquired from a streamflow collation for unregulated catchments across Australia32. Gaps in the water-balance ET time series (accounting for <5% of monthly records) were filled using simulations from the Australian Water Availability Project33, further detailed in Supplementary Section 1.

Study basins. The 190 study basins were chosen based on the completeness of streamflow records (>95%) and the extent of irrigated and farmed land (<5% of basin area). The basins were classified into wet, sub-humid, semi-arid and arid using the climatological aridity index $A$ ($A = PET/P$, where $PET = $ annual mean potential ET and $P = $ annual mean precipitation) (see Supplementary Fig. 1 for basin locations and aridity classification). River basins with mean annual aridity index $<1$ were classified as wet, 1–2 as sub-humid, 2–3 as semi-arid and $>3$ as arid (adapted from UNEP1973). See Supplementary Section 1 for further details on basin selection and classification criteria.

Breakpoint regression. Five-year running mean NDVI values were binned according to their corresponding precipitation values. Following ref. 6, the 95th percentile value was determined for each 20-mm-wide precipitation bin separately for each running mean. Breakpoint regression was applied to the $95^{th}$ percentile values to calculate the first regression slope marking the maximum NDVI attainable for a given precipitation and the breakpoint where the vegetation–precipitation relationship plateaus and vegetation ceases to be water-limited. We then constructed time series of the slopes and breakpoints (Fig. 3) and determined linear trends for both variables. As running means were used to construct the time series, degrees of freedom were adjusted when determining the significance of trends. Farmlands, irrigated areas and wetlands were excluded from this analysis using the Dynamic Land Cover Dataset of Australia33 (see Supplementary Section 1).

CO$_2$ sensitivity coefficients. Estimation of observed CO$_2$ coefficients. Dimensionless CO$_2$ sensitivity coefficients were calculated from NDVI and ET corrected for precipitation and PET (a function of temperature and shortwave radiation). Precipitation and PET were determined using the climatic aridity index ($A$) to determine the main climatic constraints on plant growth34 and are the two first-order controls on ET (ref. 35). From equation (1) into equation (2) yields

$$E = 1.6g_aD$$

where $g_a$ is the stomatal conductance to CO$_2$, $g$ is the ratio of internal CO$_2$ concentration ($C_a$) to $C_a$ and $D$ is the vapour pressure deficit. $g$ is a function of $D$ and leaf temperature36,37 and typically takes values from 0.4–0.5 in arid climates to 0.8–0.9 in wet climates. Substitution of $g$ from equation (1) into equation (2) yields

$$E = 1.6(D/C_a)A/(1 - c)$$

Differentiating with respect to $C_a$, holding $D$ and $c$ constant, gives:

$$\sigma_{ET} = (C_a/E)\partial E/\partial C_a = \sigma_c - 1$$

where $\sigma_c$ is the sensitivity of $A$ to $C_a$;

$$\sigma_c = (C_a/A)\partial A/\partial C_a$$

Equation (4) implies that the sensitivity of $E$ to $C_a$ approaches $-1$ as the CO$_2$ fertilization effect on $A$ saturates. However, so long as $A$ is increasing with $C_a$, the sensitivity is smaller in magnitude than $-1$. The sensitivity of $A$ to $C_a$ can be calculated conservatively by invoking the coordination hypothesis (approximate equality of the carboxylation- and electron transport-limited rates of photosynthesis under field conditions: see, for example, ref. 40). With the further assumption that limitation by the maximum rate of electron transport ($I_{max}$) is not relevant in the field (because Rubisco limitation takes over at the highest light levels), we can express the assimilation rate as

$$A = \psi A_c(C_a - \Gamma)/C_a + 2(\psi + \Gamma)/C_a$$

where $\psi$ is the intrinsic quantum efficiency of $C_a$, photosynthesis, $A_c$ is the absorbed photosynthetic photon flux density and $\Gamma$ is the photosynthetic compensation point. Differentiating $A$ with respect to $C_a$, holding $\Gamma$ constant, gives:

$$\sigma_c = \Gamma/A_c(1/(\Gamma - C_a) + 2/(\Gamma + C_a))$$

Evaluating equation (7) and then (4) at 25 °C, $C_a = 370$ ppm for illustration gives $\sigma_c = 0.61$ for $\Gamma = 0.8$ and $\sigma_c = 0.38$ for $\Gamma = 0.5$.
